

A photograph of a forest stream. A large, fallen log lies across the middle of the stream. The water is calm, reflecting the surrounding green foliage. A white marker is visible in the water on the right side. The background is a dense forest with many trees.

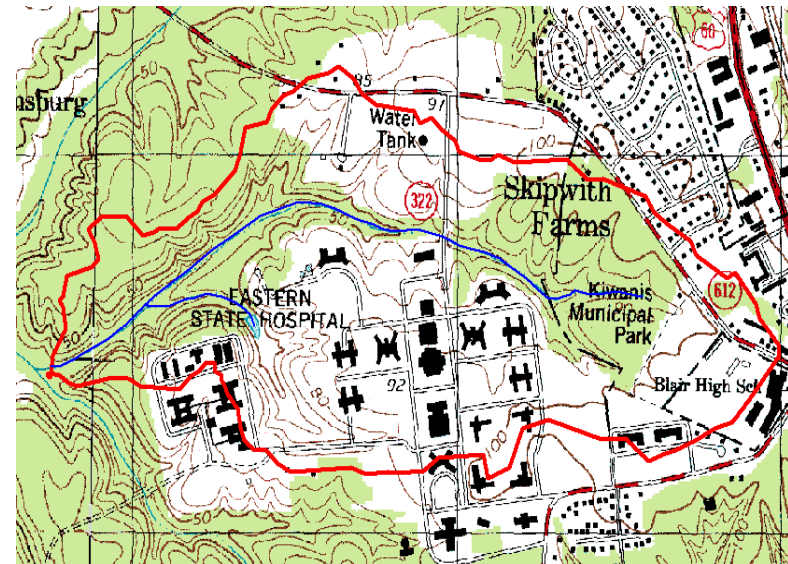

# Geomorphology along an incised channel

Catherine Noll  
advised by Greg Hancock  
with Becca Lawrence and Chris Bowles

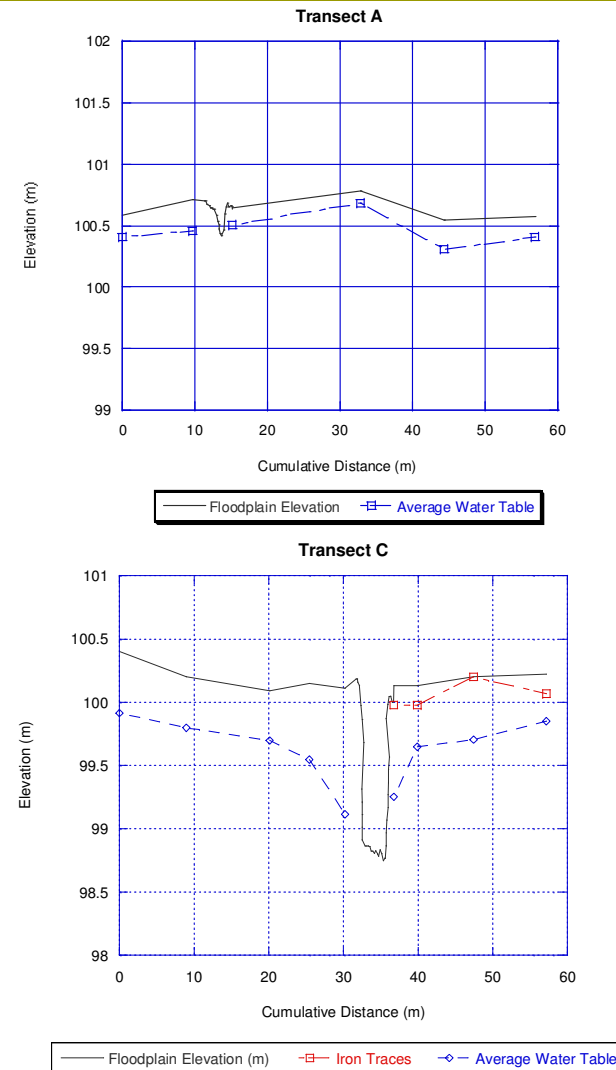

# Background

- ❑ Site: Eastern State, a moderately developed hospital with a wooded area
- ❑ Contains a perennial stream and several intermittent tributaries
- ❑ Stream and some tributaries have incised, presumably due to urbanization

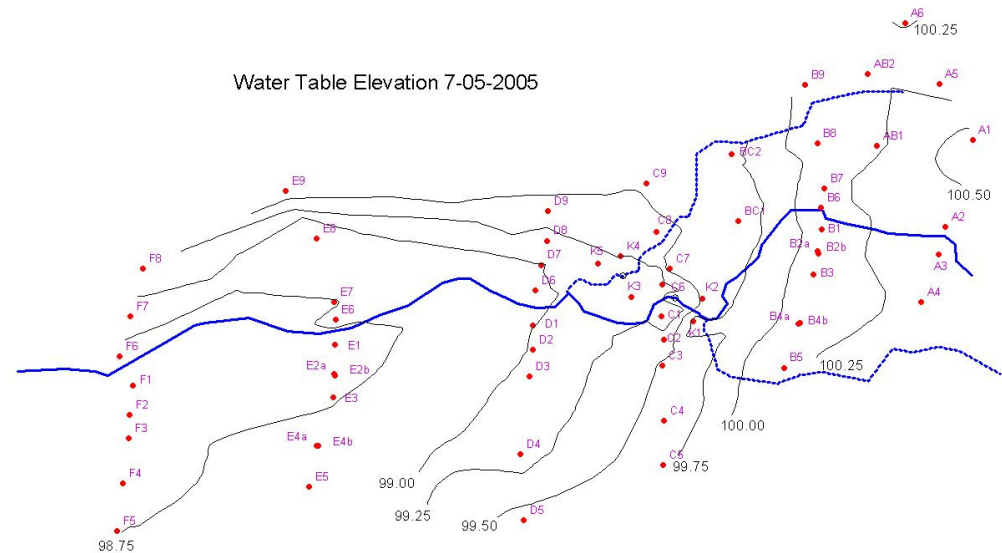

# Incision

- ❑ Occurs as runoff from urbanization increases flows through a channel
- ❑ Cuts into the streambed, deepening the channel and altering its shape and the bank shape
- ❑ Changes the flow patterns of the water table
  - Water table drops at knickpoint
  - Groundwater flow direction changes to flow into the stream
  - Increase in hydraulic head can lead to bank failure

# The Knickpoint

- A point upstream of which the channel and floodplain maintain natural condition
  - Large, well developed floodplain
  - Storm recovery
  - Fine grained, highly organic floodplain and streambed
- Downstream the channel is incised
  - Small or no floodplain
  - High erosion rates, little recovery after storms
  - Coarser grained, often soil has been eroded away entirely

# Hypotheses

---

- ❑ The knickpoint is eroding at a rate of about 1.5 meters per year; floodplain recovery occurs at a slower rate
- ❑ The stream channel will reach a geomorphic equilibrium with the “new” discharge cycle downstream of the knickpoint
- ❑ Significant differences will exist between the newly built floodplain deposits downstream of the knickpoint and the floodplain upstream of the knickpoint

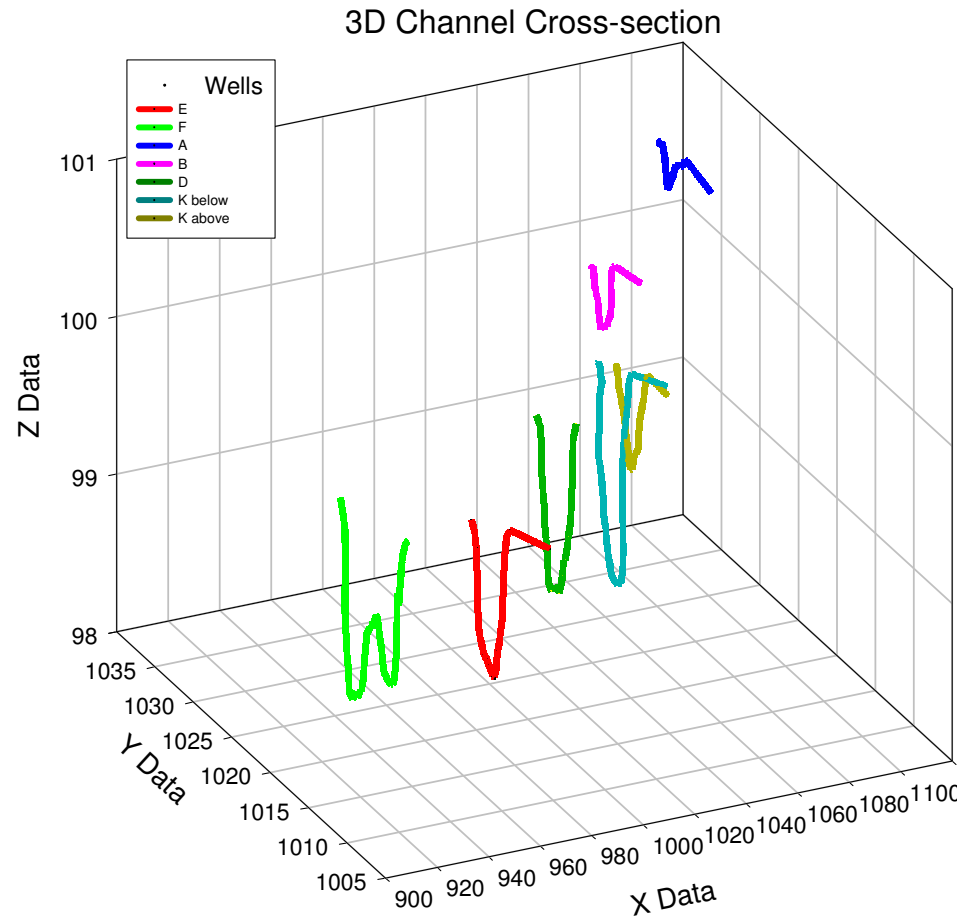

# Methods

- ❑ Wells
  - Water table monitoring
  - Stratigraphy sections
- ❑ Channel cross-sections
  - June, July, and August 2005
  - October 2001
- ❑ Erosion pins
  - Across transects
  - At knickpoint
- ❑ Survey Data

# Channel profile

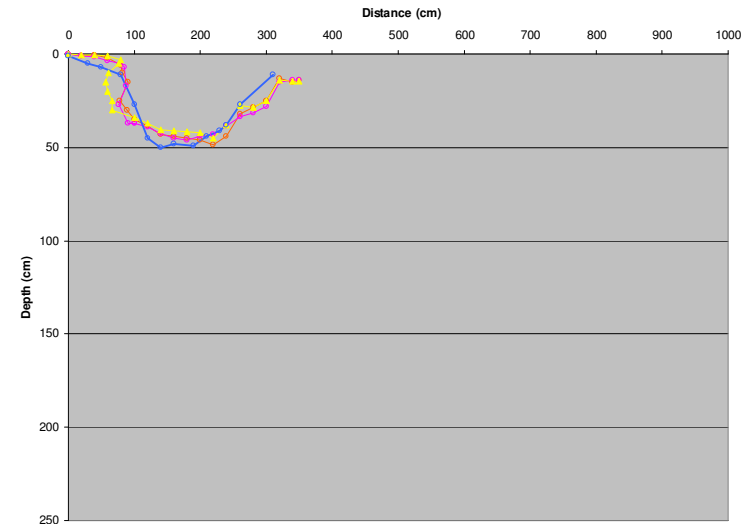

# Channel modification and equilibrium above the knickpoint

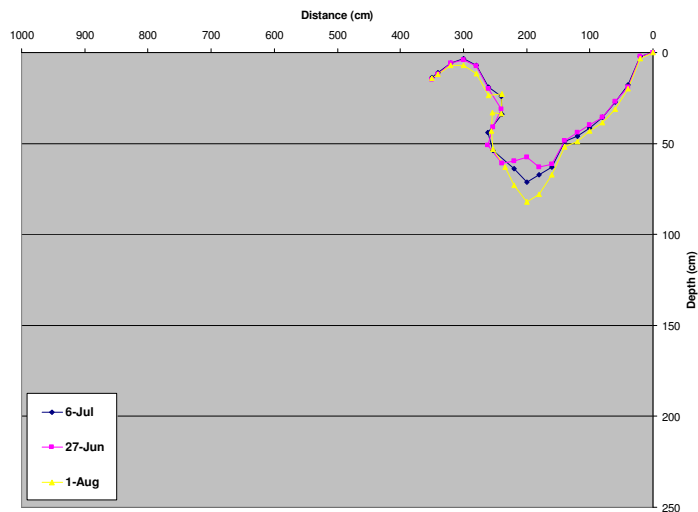

**Transect A**

**Upstream of Knickpoint: B transect**

**Transect K**

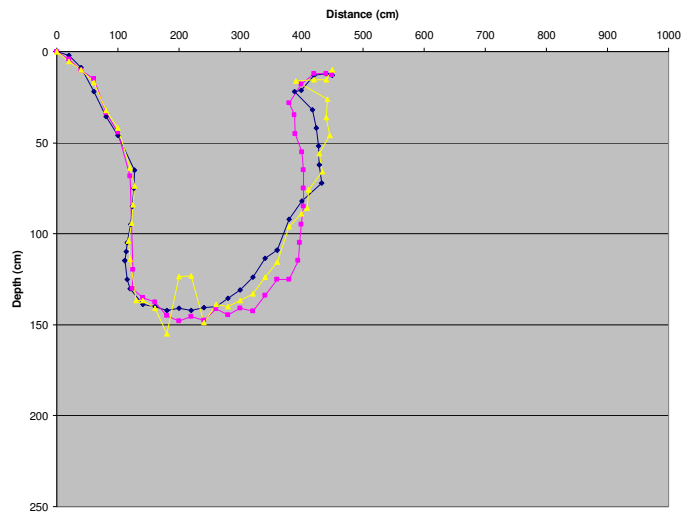

**Just Above Knickpoint**

# Channel modification and equilibrium below the knickpoint

Just Below Knickpoint

Below Knickpoint: Transect D

Before and After Knickpoint Passage: Transect C

Far Downstream of Knickpoint: Transect F

# Cross section area analysis

---

	Average size from summer 2005 x-sections	Average change between measurements	% change total 2005	% Growth since 2001
Transect A	4082 cm	145 cm	7%	
B	9471	72	2	8%
K	12099	851	14	
Just above k.p.	15707	407	5	
Just below k.p	41457	109	1	
C	47167	185	1	49
D	40828	492	2	-3
E	32340	235	1	
F	70468	1502	4	32

# Knickpoint Retreat

Retreats (cm):  
27 June – 5 July: 1.2  
5 July – 11 July: 16  
11 July – 20 July: 3.6  
**Total: 20.8 cm**

# Rates of Change

---

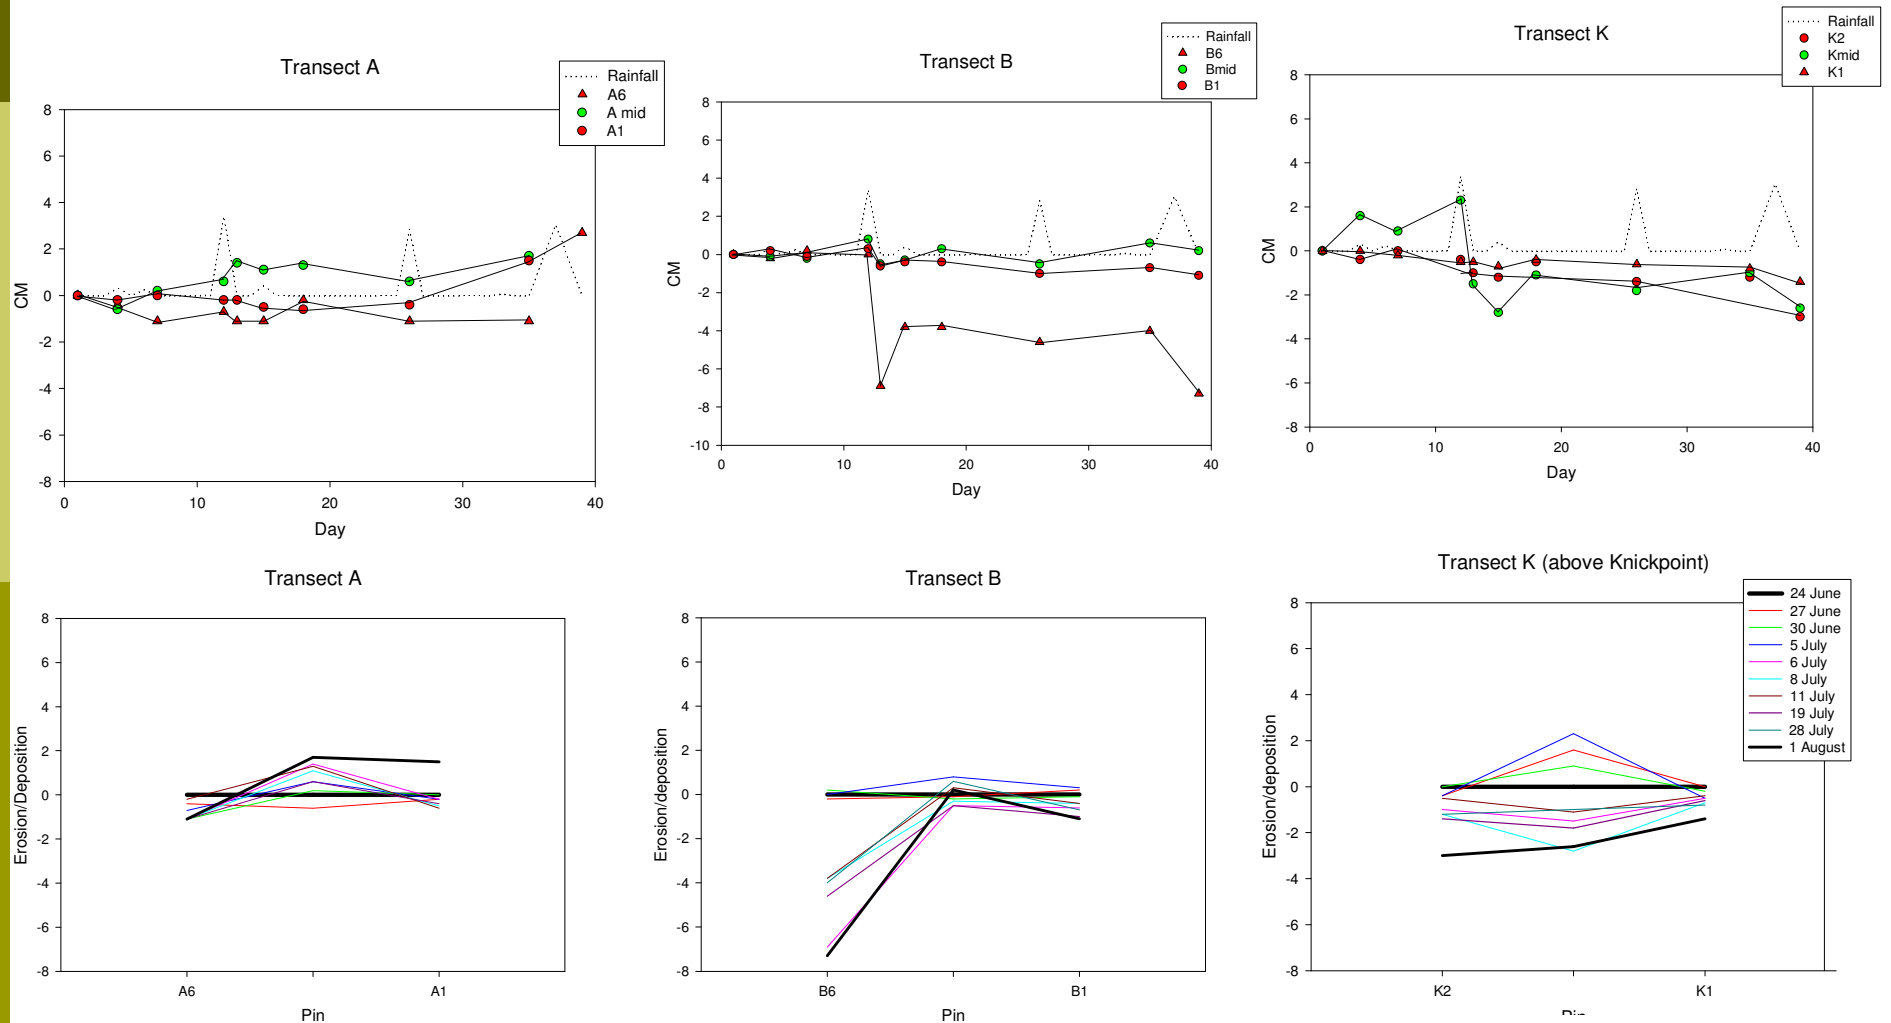

## □ Knickpoint

- Summer: 20.8 cm; extended to one year = about 1 m per year (close)
- **3.75 years: 595 cm, about 1.6 m per year**
  - Since 1950 (Eastern State development): 88 m, 10 m beyond transect E
  - If it started at F: 40 m more = 25 more years (1925)
- If the knickpoint started at F, what does this mean?

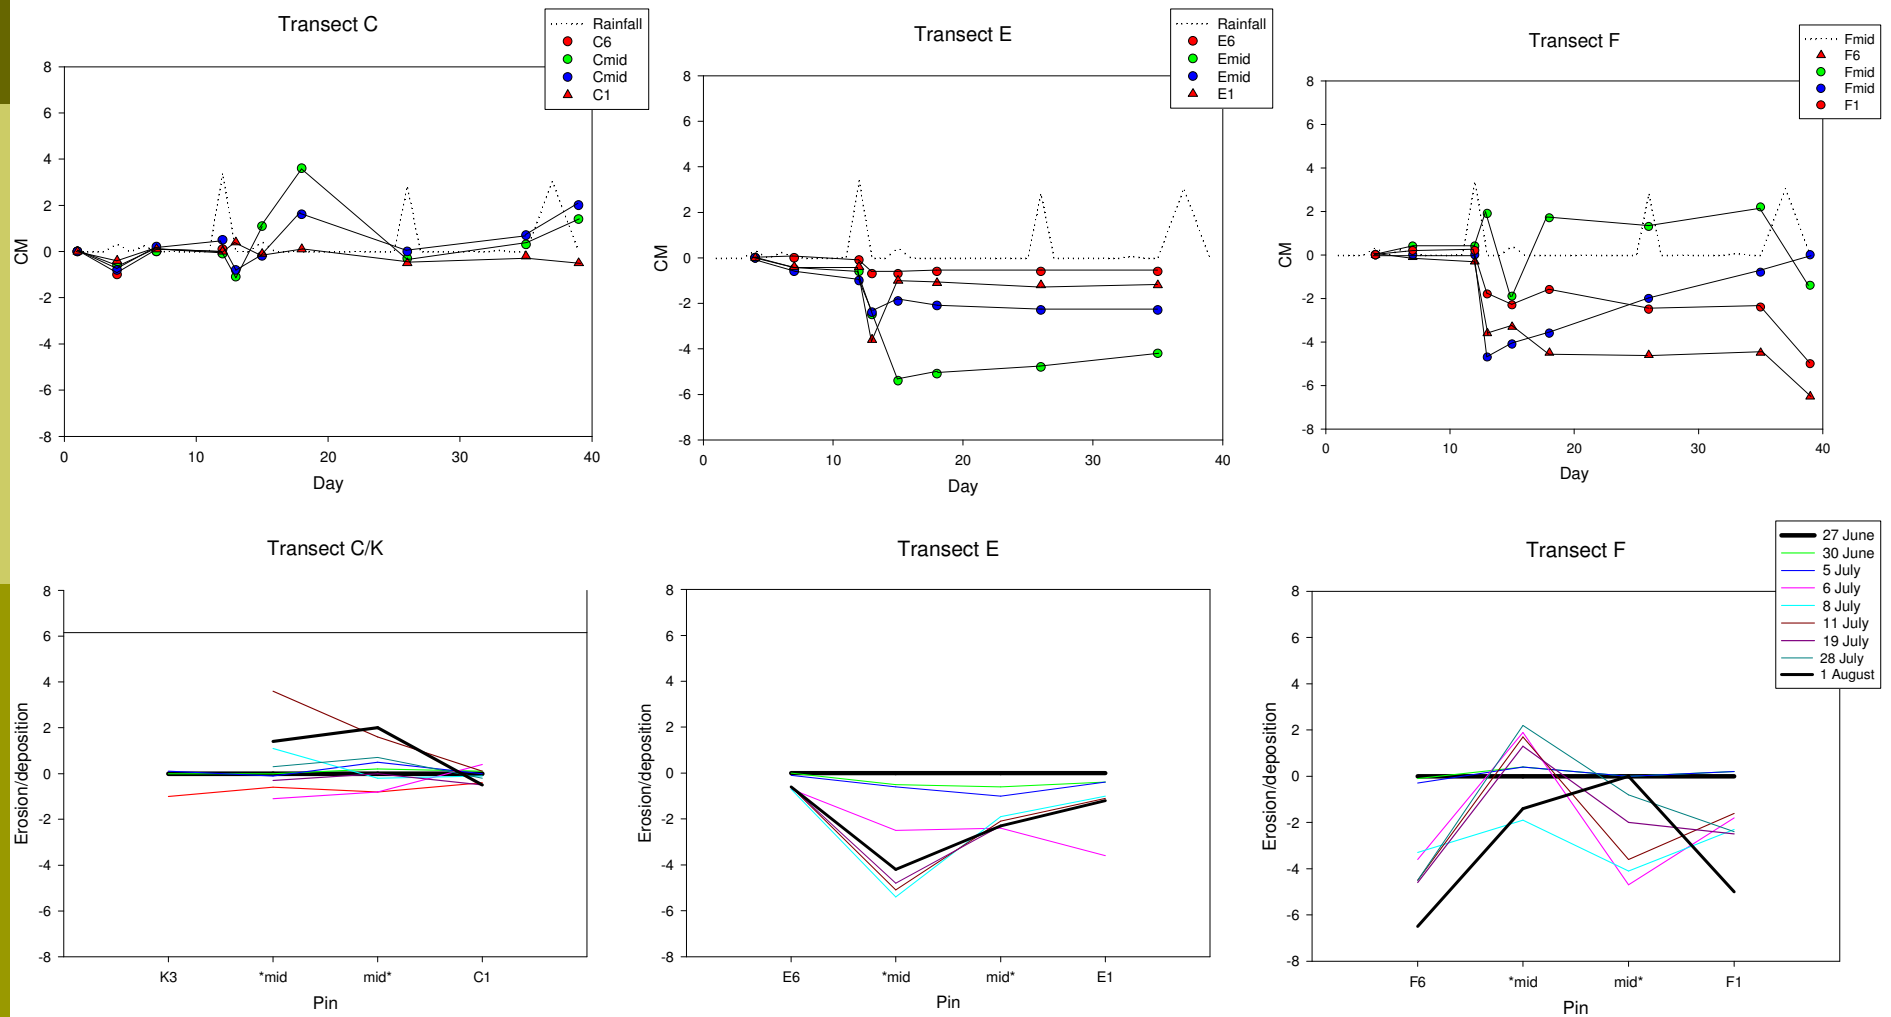

## □ Banks and floodplain

- Rapid drop in elevation following knickpoint passage
- Some immediate deposition in channel, relatively stable channel
- Deposits of coarse grains in banks following storm events leads to a slowly building floodplain
- Unclear rate of new floodplain development; still no total recovery

# Erosion and deposition above the knickpoint

# Erosion and deposition below the knickpoint

# Erosion and storm recovery

---

## Upstream of knickpoint

### □ Erosion

- Less variation in erosion and deposition; net deposition following most storms
- Deposition in channel
- Closer to knickpoint incision begins

### □ Storm reaction

- Storm response less extreme
- Banks erode more than channel far upstream
- Nearing the knickpoint channel bottom is more variable

## Downstream of knickpoint

### □ Erosion

- Close to knickpoint erratic deposition and erosion
- Farther incision still is present
- Farthest downstream deposition along channel bottom occurs less consistently

### □ Storm reaction

- Channel deposition near knickpoint
- At incision banks erode less quickly than channel
- At newly building floodplain instability is still high

# Floodplain Stratigraphy

Transect B

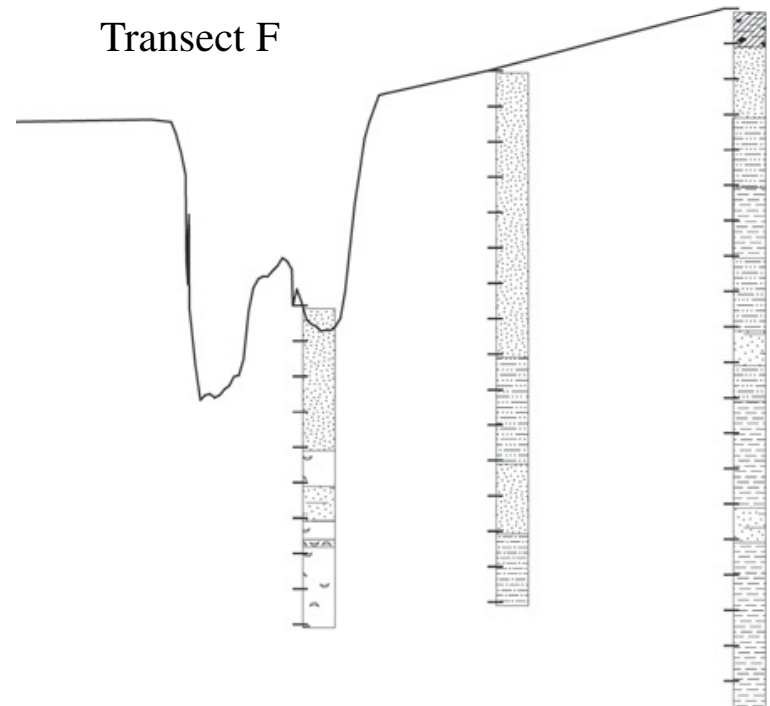

Transect C

Transect E

Transect F

# Implications

---

- ❑ Knickpoint past
  - Could have started around transect E in response to incision, assuming a linear rate of about 1.6 m/year
  - Could have started at transect F given a nonlinear rate or other development conditions
- ❑ Knickpoint future
  - 71.5 m to transect A, about 44.5 years assuming linear rate
  - What then?
- ❑ Bank/floodplain recovery rate
  - Upwards of 50 years for current state
  - Still less stable than A; water table recovery has not fully occurred
- ❑ Recovered floodplain
  - Larger grain size
  - Less organic content
  - Total recovery?

# Future Directions

---

- ❑ More on recovery rates
- ❑ Permanent changes to the stream channel and ecosystem?
- ❑ Grain size and stratigraphy analyses in the channel and floodplain
- ❑ Pore water pressure and bank failure measurements
- ❑ Remediation and prevention techniques
